A Novel Explicit Disturbance Model-based Robust Damping of Inter-Area Oscillations through MTDC Grids Embedded in AC Systems

Abhishek Banerjee, Student Member, IEEE, Nilanjan Ray Chaudhuri, Senior Member, IEEE, and Rajesh Kavasseri, Senior Member, IEEE

Abstract—This paper presents a novel approach to damp inter-area oscillations by designing a robust multi-input multi-output (MIMO) supplementary controller for Multiterminal DC (MTDC) systems embedded in AC grids. The key idea to achieve robustness lies in explicitly modeling the MTDC current injection as disturbances using an $\mathcal{H}_{\infty}$ mixed-sensitivity formulation in the Linear Matrix Inequality (LMI) framework. Control directions are established by selecting wide-area feedback signals and the Relative Gain Array computation. Robustness is assessed through dynamic simulations for scenarios including: (a) disturbances on the AC side, (b) disturbances on the DC-side such as loss of a converter pole including actuator, (c) partial loss of feedback signal, and (d) communication latencies. The performance of the proposed controller is compared against the conventional $\mathcal{H}_{\infty}$ based design, using a 4-terminal DC grid embedded within the New England-New York test system. The results suggest that the proposed approach demonstrates superior performance following DC-side disturbances, actuator outages, and latency.

Index Terms—Linear Matrix Inequality (LMI), Mixed-Sensitivity, Explicit Disturbance Modeling, Inter-area Oscillations, Multiterminal DC (MTDC), Robustness, $\mathcal{H}_{\infty}$

I. INTRODUCTION

VOLTAGE Source Converter (VSC)-based Multiterminal DC (MTDC) grids are beginning to show significant promise in integrating offshore wind resources to onshore grids - thus attracting recent research attention towards modeling [1], [2] and control [3], [4] of such systems. In general point-to-point HVDC schemes suffer from certain issues, which can be overcome by an MTDC grid. As a result, such systems can also be beneficial for onshore installations. The advantages of MTDC grids include: (a) Improved reliability in face of a single-point failure, (b) Reduced capacity and reserve capacity requirement since the peak demand of different AC systems do not occur at the same time, (c) Reduced curtailment from wind farms, (d) reduced variability in renewable generation, ease of annual and preventive maintenance of the generators and the converter systems and energy trading between multiple regions like today’s AC power systems, and (e) Lower energy cost. For further explanation on points (a) (d), please refer to [11], and for point (e), please see [9], [10]. The operators of these MTDC grids connected to AC systems with multiple areas will face the typical challenges of stabilizing poorly-damped inter-area oscillations. The idea that VSC MTDC converters can provide damping support to the surrounding AC system by virtue of their ability for fast modulation of active power injections has been explored in recent literature [5]–[8], [11], [12] to design supplementary controllers. In this emerging area, it is important as pointed out in [6] to understand how the choice of controller structure influences improvements to dynamic system performance. Thus motivated, our goal is to design a supplementary controller, which can damp multiple modes and remain robust even after DC-side contingencies including actuator outages occur. The novelty lies in explicitly incorporating the MTDC current injection as disturbances in the control design using an $\mathcal{H}_{\infty}$ mixed-sensitivity formulation in the Linear Matrix Inequality (LMI) framework. This allows the control performance to be robust even when there are failures on the DC side, an aspect overlooked in recent literature. We summarize our salient contributions while drawing distinctions from prior related work as follows:

Unlike [6]–[8], [11], [12], we incorporate robustness against
DC grid disturbances into the design formulation itself and demonstrate control performance in the wake of DC-side contingencies including converter outages. To that end, the design problem presented here includes disturbance rejection into control design by introducing a novel explicitly modeled disturbance plant as opposed to the conventional way of modeling disturbances in the LMI problem in the $\mathcal{H}_\infty$ framework, as in our prior work in [12]. This has not been reported in any prior work on MTDC systems. Moreover, we have taken into account a true MIMO design by considering two converter stations in the control design formulation to damp the targeted inter-area modes, as opposed to using only two poles of a single converter station as in [12]. This presents a tough challenge in determining the control directions in an MTDC system due to increased interactions, which has been established by RGA computations. Furthermore, robustness has been assessed on several major outages, feedback signal loss, and communication latencies. A comparison has been done with the prevailing standard $\mathcal{H}_\infty$ design for power oscillation damping to demonstrate the benefits of the proposed design over an existing technique.

Unlike [7], [8] where a single mode of interest is considered, we show that the proposed method can target multiple poorly damped modes of interest and improve their damping significantly without compromising other non-targeted modes. Unlike [11] where essentially point-to-point DC links are considered to test the control strategy, we demonstrate control performance on truly MTDC grids embedded in the AC system.

We emphasize that the MTDC system or its placement is not considered solely for the purpose of damping improvement for AC systems. Neither do we consider $\mathcal{H}_\infty$-based design blindly as a “black-box” tool for robustness. Instead, our key contributions lie in modifying the design approach itself by explicitly modeling disturbances, which allows the problem to be cast in terms of an $\mathcal{H}_\infty$ optimization. This renders our approach generic and applicable to hybrid systems regardless of the size or placement of the MTDC system within the AC system.

The paper is organized with modeling aspects described in Sec. II, control formulation and solution in Sec. III, system description and signal selection in Sec. IV, simulation results in Sec. V, and conclusions in Sec. VI.

II. MODELING AND CONTROL OF MTDC GRID

We consider a bipolar VSC-MTDC grid with a metallic return network. Converters are represented by their averaged models and transmission lines between converter stations are represented by $\pi$-section models. Figure 1 shows the $i^{th}$ converter station with positive ($p$) and negative poles ($n$). Further details can be found in [2], [13].

A. Inner and Outer Control Loops

As shown in Fig. 2, the converter stations are modeled and controlled using well-known decoupled vector control strategy for individual generator models [2], [13]. The PI controller shown in Fig. 2 derives the $X - Y$ frame to the other stations [3]. The real power reference $P_{pcck}$ is modulated using control input $P_{mod}$ for power oscillation damping.

As shown in Fig. 3 the converter stations are modeled and controlled using well-known decoupled vector control strategy in the $d-q$ frame. We denote this frame as the $X - Y$ frame to avoid conflict with the $d-q$ frame notations commonly used for individual generator models [2], [13]. The PI controller shown in Fig. 2 derives the $X - Y$ frame for the inner current control loop of the positive pole converter. An identical control scheme is used for the negative pole.

B. Integration with Surrounding AC System

The differential-algebraic equation model of the multimachine AC system is built on a current injection framework. Similarly, the MTDC portion is also modeled using this current injection framework. Interface of the converter and controller models along with the DC network model is well understood and not presented here. Interested readers are referred to [13] for details.

III. CONTROL FORMULATION AND DESIGN

A. Explicit Modeling of Disturbance Rejection

Our key contribution is in framing a robust control problem where DC-side contingencies in the MTDC grid can be
incorporated as a disturbance in a LMI formulation. Since the MTDC portion is modeled on a current injection framework, any disturbance on the DC side will induce corresponding changes in the current injections into the AC grid. In turn, this will perturb the currents \( I_{gy} \) and \( I_{gy} \) in the inner current control loop of converter station poles, which have been modeled in the \( X - Y \) reference frame (see Fig. 3). Since our model consists of positive and negative poles in each converter station, this perturbed current can be resolved into four such current components \( I_{g/n}^{px} \) and \( I_{g/n}^{py} \) for both poles of a converter station, Fig 4. These current components can be further combined into the current injections at the positive and the negative poles \( I_{g/n}^{px} \) of the converters, see Fig 4.

Therefore, the current \( I_{pcc} \) at the point of common coupling (PCC) comprising the current injections of the positive and negative poles is modeled as the disturbance input \( d \) to the MTDC grid. Figure 4 represents the complete modeling of the disturbance plant \( G_d(s) \) where in a nutshell, the input are the injected currents from the positive and negative poles of the \( i^{th} \) converter station and the output are the feedback signals \( y_d \) used for damping control. Note that the synthesized disturbance plant \( G_d(s) \) has the same poles as in the plant \( G_u(s) \), which represents the MIMO linear model of the system between control input \( u \) denoted by \( P_{mod} \) signals shown in Fig. 2 and the feedback signals denoted as \( y_p \) used for damping control. The Mixed-Sensitivity formulation involving plants \( G_d(s) \) and \( G_u(s) \) is described next.

### B. Mixed Sensitivity Formulation

With the explicitly modeled disturbances, we translate the Stacked Sensitivity problem to an \( H_{\infty} \) optimization.

\[
G_d = C(sI - A)^{-1}B_d, \quad G_u = C(sI - A)^{-1}B_u
\]  

The proposed control scheme is depicted in Fig. 6 where \( d, r \) are the exogenous input including disturbances. The regulated output are \( z_1 \) and \( z_2 \), and being a regulator problem, the reference \( r = 0 \).

The generalized plant \( P \), including the weighting filters and the disturbance plant can be partitioned as,

\[
P = \begin{bmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{bmatrix}
\]  

such that its parts resemble with \( z, v, w, \) and \( u \) and in the generalized control configuration as,

\[
z = P_{11}w + P_{12}u \\
v = P_{21}w + P_{22}u
\]  

Expanding this to the proposed mixed-sensitivity scheme as shown in Fig. 6, the generalized plant \( P \) is obtained as,

\[
P = \begin{bmatrix} 0 & W_1G_d \\ W_1 & 0 \end{bmatrix} \begin{bmatrix} G_d & 0 \\ 0 & G_u \end{bmatrix}
\]
After the interconnecting structure has been used to determine $P$, the next step is to synthesize a sub-optimal controller, and combine the controller in the structure in Fig. 6, to obtain the closed-loop form $N$, which represents the closed-loop transfer function, see Fig. 7, from the exogenous input to the regulated output, i.e., from $\frac{r}{d}$ to $z$. $N$ is calculated using a Lower Fractional Transformation (LFT), [15] which yields,

$$N = P_{11} + P_{12}K(I - P_{22}K)^{-1}P_{21} \approx F_1(P, K)$$

(5)

The $H_\infty$ optimization problem now boils down to find a stabilizing controller $K$ to minimize the cost function,

$$\left\| \begin{bmatrix} W_1S & W_1SGdW_3 \\ W_2KS & W_2KSGdW_3 \end{bmatrix} \right\|_{\infty}$$

(6)

which is the $H_\infty$ norm of the transfer function from $\frac{r}{d}$ to $z$. Since in our case $r = 0$, the cost function in (6) simplifies to (7). The goal of the $H_\infty$ design is minimizing (7) for guaranteed robustness.

$$\left\| \begin{bmatrix} W_1SGdW_3 \\ W_2KSGdW_3 \end{bmatrix} \right\|_{\infty}$$

(7)

This $H_\infty$ optimization problem in (7) involves solutions of LMI’s for minimizing $\|N\|_{\infty}$, which guarantees asymptotic stability. This is a well studied aspect and it involves the solutions of LMI’s in regard to the bounded real lemma [16], [17], using Schur’s formula for the determinant of a partitioned matrix [15], and is not discussed here. This LMI problem can be solved by using the Robust Control Toolbox in Matlab [22]. An additional constraint to place all poles on the left-half of the $s$-plane within a conic sector was considered to ensure the desired closed-loop damping ratio [18], [19], [20].

IV. TEST SYSTEM AND DAMPING CONTROLLER SYNTHESIS

A. Test System

The MTDC grid consists of four converter terminals, which are interconnected to the 16-machine NETS-NYPS system [14] as shown in Fig. 8. The nominal real and reactive powers at the PCC of the converter stations are annotated in this figure. All generators are represented by subtransient models and eight of them ($G_1$ – $G_8$) are equipped with the IEEE DC1A excitation system. The rest of the machines are under manual excitation control, and $G9$ is equipped with a static exciter and a power system stabilizer (PSS). Constant impedance type loads are considered. The dynamic data and base case conditions are as in [14].

B. Signal Selection Criterion

Eigenvalue analysis reveals that the system has two poorly damped inter-area modes of interest: (0.2 Hz at 1.5 %) and (0.47 Hz at 3.3 %), which are shown in Table I. Since the specific objective of the damping controller is to improve the damping of these two modes without negatively impacting the others, it is necessary to learn the interaction among input and output, and identify the most appropriate control directions.

**TABLE I**

</tbody>
</table>

To that end, residue analysis was performed for appropriate selection of feedback signals and control input. In MIMO systems, the angle of the residue is important as well. The phase compensation required at each modal frequency is closely related to the phase angles of the residue [21]. The residue analysis of the linear model shown in Table II reveals that the best selection of feedback signals are $P_{27-53}$ across mode 1 and $P_{13-17}$ across mode 2 whereas converter stations #1 and #3 are the best choice for the control input.

**Relative Gain Array (RGA):** In a true MIMO sense, RGA is used to corroborate the input/output pairing choices obtained from the signal selection. The RGA of a non-singular square matrix $G$ is a square matrix defined as

$$RGA(G) = \Lambda(G) \equiv G \times (G^{-1})^T$$

(8)

where $\times$ denotes element-by-element multiplication (the Schur or Hadamard product). RGA can also be computed for non-square matrices by the method of pseudoinverse [15].

RGA values are useful to guide the selections because: (a) values close to 1 show favourable pairing [24] for centralized control scheme and (b) negative entries indicate too much interaction and not suitable for pairing. In our design, RGA was calculated for the nominal plant $G_n(s)$ with results shown in Table III, where the input are the columns and the feedback signals are the rows. The analysis clearly affirms with the input/output pairing choices made earlier by residue calculations.

As seen in Table III, for the feedback signal $P_{13-17}$, converter station #3 shows the best possibility of pairing with RGA value being closest to unity. Although converter station #4 negative pole has a closer value than #3 negative pole, we choose #3 as the best possible case because it has a higher modal controllability index for mode 2. For feedback signal $P_{27-53}$, converter #1 stands closest to unity which validates

our signal selection.

C. Process for Damping Controller Synthesis

1) Damping Criterion: The closed loop poles of the critical modes are placed within a conic sector with inner angle \( \theta \) and the apex at the origin [19], [20] to ensure a minimum damping ratio \( \zeta_{\text{min}} = \cos(\theta/2) \). A minimum damping ratio of 6.5\% was chosen for both modes which corresponds to an inner angle of 3.0115 radians. The design achieves this specification for both the inter-area modes.

2) Weighting Filter Selection: The weighting filters \( W_1, W_2 \), and \( W_3 \) in Fig 6 are selected in light of the following requirements:

- Selection of \( W_1 \): The disturbance \( d \) as in Fig 5 is a low frequency signal and is hence penalized with a low-pass filter with the bandwidth equal to the disturbance signal \( d \). Iteratively, \( W_{1\text{,init}} \) was best found as (9), where \( K_1 = 0.05 \). In order to scale it to the plant gain, a 3-stage cascade is used to obtain \( W_1 \), resulting in a 6\(^{th} \) order filter.

\[
W_{1\text{,init}}(s) = K_1 \frac{0.25}{s^2 + s + 0.25}
\]  

(9)

The added advantage of the cascade was the steepness of the low pass filter, which proved to be very effective for the disturbance attenuation at the low frequencies, and to achieve improvement in damping for the required modes. \( W_1 \) dominates in the frequency range of \((0 - 8.5 \text{ rad/s})\). It should be noted that all the modes of interest are within this frequency range.

- Selection of \( W_2 \): The filter \( W_2 \) is selected to be a highpass filter with crossover frequency approximately equal to the closed loop bandwidth of the system. This improves control effort minimization at higher frequencies. The cut-off frequency for the high-pass filter was set to 150 rad/s to limit the magnitude of the closed loop poles of the controller. \( W_2 \) was also obtained after cascading the high-pass filter \( W_{2\text{,init}} \) (10) in series resulting in a 6\(^{th} \) order high-pass filter, where \( K_2 = 0.01 \). In order to ensure that the weight \( W_1 \) dominated at the low frequencies for successful disturbance attenuation, \( W_2 \) was designed to attain a low frequency gain of \(-572 \text{ dB} \).

\[
W_{2\text{,init}}(s) = K_2 \frac{s^2}{s^2 + 120s + 3600}
\]  

(10)

- Selection of \( W_3 \): \( W_3 \) is weighted for the disturbance plant input matrix. It is selected as \( W_3 = \alpha I \), with \( \alpha \) designed for disturbance rejection by scaling the input of the disturbance plant as close as possible to the nominal plant. After an iterative process, \( \alpha = (50 \times 10^{-6}) \) is obtained to satisfy these criteria.

3) Damping Controller Design: A self-explanatory flowchart is shown in Fig. 9, which summarizes the damping controller design methodology. The original plant and the disturbance plant are reduced to a 20\(^{th} \) order equivalent by Schur Balanced Truncation [15], see Fig. 10.

The reduced plants capture the targeted inter-area modes of 0.201 Hz and 0.475 Hz. As shown in Fig. 9, the objectives of the control design is simultaneous disturbance attenuation, explicitly modeled disturbance rejection, and control effort minimization. This resulted in a 56\(^{th} \) order controller, which was reduced to 28\(^{th} \) order - the singular value plots are shown in Fig.11(a). The designed controller modulates the real power reference of the positive and negative poles of converter stations #1 and #3. The control design was performed using the Robust Control Toolbox in Matlab [22]. Table I highlights the closed-loop poles of the system with the reduced controller, which shows that a settling time of less than 15.0s is achieved for the targeted modes without compromising the well-damped modes.

Damping ratios, frequencies and settling times of the inter-area modes in test system with standard $\mathcal{H}_\infty$ control

Table IV shows the closed-loop poles with the standard $\mathcal{H}_\infty$ design. This is the best possible closed-loop damping performance we could achieve, albeit with $\zeta_{\text{min}} = 15\%$ as design criterion, as opposed to $\zeta_{\text{min}} = 6.5\%$ used for the proposed method. Attempt to increase closed-loop damping by further increasing $\zeta_{\text{min}}$ lead to non-convergence. It can be seen in Table IV that the closed-loop damping is slightly inferior compared to the explicit disturbance rejection design, in Table I.

Figure 12 shows the comparison of control effort between the standard $\mathcal{H}_\infty$ design and the proposed design when a pulse disturbance is applied at the input of the closed-loop full-order linearized plant. The proposed controller produces slightly better damping performance at significantly lesser control effort.

E. Measures of Robustness

Robustness in the design can be observed from the infinity norm of the weighted sensitivity and the control times sensitivity, according to the Small Gain Theorem and the Bounded Real Lemma [15], [16]. Both the weighted functions in our proposed design satisfy the robustness criteria: $\|W_1 S\|_\infty = 1.2523 \times 10^{-4}$, $\|W_2 K S\|_\infty = 7.3755 \times 10^{-5}$. They also satisfy the robustness criterion with the standard

control scheme. The standard $\mathcal{H}_\infty$ design philosophy is kept the same as in [12]. The same reduced-order nominal plant was used for the control design. In order to maintain uniformity in design, the same weights (9), (10) were chosen, and cascading was performed in a similar fashion as in case of the explicit disturbance rejection design. This resulted in a $56^{th}$ order controller, which was reduced to $28^{th}$ order - the singular value plots are shown in Fig.11(b).

Another measure of robustness is the smallest unstructured inverse input multiplicative perturbation at the sensitivity function that can destabilize the system. This parameter can be evaluated by placing a bound on the largest singular value of the sensitivity [23]. If we assume the perturbation as \( \delta_0 \), then robust stability requires \( \sigma \left( \frac{1}{1 - L} \right) < \frac{1}{\delta_0} \), where \( L = KG \) is the open loop gain at the plant input channels. The singular values of the input plant sensitivity are plotted in Fig. 13, which correspond to the smallest unstructured inverse input multiplicative perturbation.

**Fig. 13.** Input plant sensitivity subject to the designed controllers

From Table V, it can be seen that \( \delta_0 \) for the proposed controller is almost twice of that of the standard \( H_\infty \) controller. This indicates that the proposed control has a greater bound for the disturbance input, i.e., any perturbation in the input channels of the plant will have to be almost double the amount as compared to the standard \( H_\infty \) design to destabilize the system. This ensures that the disturbance attenuation property of the proposed control design is superior, which makes it more robust to disturbance input than that of the existing method.

The phase and gain margins at the input channels [23] are calculated using (11) and shown in Table V. The gain and phase margins at the input channels are comparatively better for the proposed control.

\[
GM = \frac{1}{1 + \delta_0}, \quad \frac{1}{1 - \delta_0}, \quad PM = \pm \cos^{-1} \left[ 1 - \frac{\delta_0^2}{2} \right] \tag{11}
\]

**Remark:** For an MTDC grid connecting offshore wind farms to onshore AC system, a combination of onshore converter stations and offshore wind farms can be used as actuators. The real power reference of the offshore wind farms can be modulated using remote PMU signals from the onshore AC grid.

**V. SIMULATION RESULTS**

To demonstrate robustness of the proposed control scheme, simulations were carried out for multiple contingencies, which trigger the inter-area modes. Unlike earlier works, which considered only AC-side faults, we illustrate performance following major AC as well as DC-side disturbances. From now on, we will use the legend “Explicitly modelled DR” to represent the proposed explicitly modeled disturbance rejection controller response in the plots.

**A. Major Tie-Line Outages**

We have considered outages of one of the tie-lines in each of the double-circuit lines connecting buses (18–42), (18–49), (27–53) and (40–41), see Fig. 8, following a 3-phase, 5-cycle fault. The faults were simulated near bus 18, 49, 27, and 40, respectively. Notably, these tie-lines interconnect the five areas in the meshed AC-MTDC system.

**Fig. 14.** Dynamic performance of the system following a 3-phase fault near bus 18 cleared after 5-cycles by the outage of one of the double-circuit lines connecting buses 18 and 42, Fig. 8, at \( t = 1.0s \).

**Fig. 15.** DC voltage of the converter poles following a 3-phase fault near bus 18 cleared after 5-cycles by the outage of one of the double-circuit lines connecting buses 18 and 42, Fig. 8, at \( t = 1.0s \).

Figures 14, 16, 18, and 19 show effective damping for outage of lines (18–42), (18–49), (27–53) and (40–41), respectively. It can be seen from Figs 14, 16, 18, and 19 that the proposed method produces similar damping performance compared to the standard \( H_\infty \) control, in case of major tie-line outages in the grid. This is expected since both approaches are robust control design methods. The DC voltages of the converter stations’ negative and positive poles are plotted in Figs 15, 17, and 20 in the event of outage of the lines (18–42),
Explicitly modelled DR

Standard $H_\infty$

Explicitly modelled DR

Fig. 17. DC voltage of the converter poles following a 3-phase fault near bus 49 cleared after 5-cycles by the outage of one of the double-circuit lines connecting buses 18 and 49, Fig. 8, at $t = 1.0s$.  

Fig. 18. Dynamic performance of the system following a 3-phase fault near bus 27 cleared after 5-cycles by the outage of one of the double-circuit lines connecting buses 27 and 53, Fig. 8, at $t = 1.0s$.  

Fig. 19. Dynamic performance of the system following a 3-phase fault near bus 40 cleared after 5-cycles by the outage of one of the double-circuit lines connecting buses 40 and 41, Fig. 8, at $t = 1.0s$.  

Fig. 20. DC voltage of the converter poles following a 3-phase fault near bus 40 cleared after 5-cycles by the outage of one of the double-circuit lines connecting buses 40 and 41, Fig. 8, at $t = 1.0s$.  

B. Converter Station Outage

1) Negative pole outage at converter station #2  
Figures 21 and 22 show the dynamic performance of the system following the outage of the negative pole of converter station #2. It can be seen that – (a) At $t = 1.0s$ the real power output of converter #2 negative pole becomes zero; (b) The explicitly modelled disturbance rejection $H_\infty$ damping controller is able to damp the oscillatory modes better than the standard $H_\infty$ controller; (c) Major line power flows have been shown in Fig. 21 whereas Fig. 22 shows DC voltages of the negative and positive poles of the converter stations.  

2) Actuator outage: Negative pole outage at converter station #3  
Converter station #3 was used as an actuator in the control design. The outage of one pole of converter #3 may have serious consequences, if it is not considered in the design phase of the controller. Figure 23 shows that despite the outage of the actuator, the proposed damping controller demonstrates strong disturbance rejection properties. The actuator #3 outage can been seen from the first subplot in Fig. 23.  

It can be observed that the proposed controller produces better damping performance in the event of actuator outage-a
The damping performance of the standard $H_\infty$ controller is comparatively inferior to the proposed controller in case of major DC-side outages, see Figs 21, 23. Moreover, the DC voltage profiles in the converter station poles in Figs 22 and 24 show huge excursions with the standard $H_\infty$ control due to higher control effort requirement. On the contrary, the proposed controller produces lesser fluctuations in the DC voltages. These results confirm the benefits of the novel concept of explicitly modeling the disturbances for controller design, as this approach produces better damping performance with lesser control effort for AC as well as DC-side outages.

C. Feedback Signal Loss

Figure 25 shows the dynamic performance of the damping controller with the loss of the feedback signal $P_{13\rightarrow 17}$, following the outage of one of the double-circuit lines connecting buses 18 and 49 at $t = 1.0s$. A similar damping performance can be observed for both the design approaches.

D. Communication Latency

To demonstrate the robustness of the controller performance following (a) converter #2 negative pole outage and (b) outage of one of the double circuit lines connecting buses 18 and 42 are studied in presence of a 100 ms latency in the feedback signals. The effectiveness of the controller in presence of
latency can be seen in Fig. 26 following the converter and the line outage scenarios.

It is interesting to note that for the AC line outage, see the last subplot in Fig. 26, the standard $H_\infty$ controller produces a similar performance as the proposed controller. However, in case of the DC outage, shown in the first two subplots in Fig. 26, the standard $H_\infty$ controller fails to maintain stability. This further substantiates the need for explicitly modeling disturbances in the control formulation to take into account such events that can cause the standard $H_\infty$ control technique to fail.

VI. CONCLUSION

This paper presents a new approach for robust power oscillation damping in MTDC grids connected to AC systems. The novelty consists in modifying the $H_\infty$ control design approach where disturbances can be viewed and accounted explicitly in terms of MTDC current injections. This problem is solved by an updated mixed sensitivity formulation in the Linear Matrix Inequality (LMI) framework. The resulting MIMO controller uses wide-area signals to stabilize poorly-damped inter-area modes without compromising well-damped modes. Control performance and robustness are assessed with dynamic simulations on a 16-machine 5-area system connected to a 4-terminal asymmetric bipolar MTDC grid. The unique aspect of the proposed controller is its robustness to severe disturbances on the AC as well as DC side - including loss of actuators. In addition, the proposed controller is able to maintain acceptable performance in the wake of communication latencies and partial signal loss. The proposed design approach shows superior performance compared to a standard $H_\infty$ design.
